ABSTRACT: The Ferrier rearrangement reaction is crucial for the synthesis of pharmaceuticals. Although its mechanism was described more than 50 years ago, the structure of the intermediate remains elusive. Two structures have been proposed for this Ferrier glycosyl cation: a 1,2-unsaturated cation that is resonance-stabilized within the pyranose ring or a cation that is stabilized by the anchimeric assistance of a neighboring acetyl group. Using a combination of gas-phase cryogenic infrared spectroscopy in helium nanodroplets and first-principles density functional theory, we provide the first direct structural characterization of Ferrier cations. The data show that both acetylated glucal and galactal lead to glycosyl cations of the dioxolenium type.

In 1917, Emil Fischer reported a class of 1,2-unsaturated monosaccharide building blocks, so-called glycals.1 Almost 50 years later, the rich chemistry of glycals was exploited by Robert J. Ferrier, who first accurately described the mechanism of the allylic rearrangement in protected glycals upon nucleophilic substitution, today known as the Ferrier rearrangement (Scheme 1).2,3 In this reaction, the C3-acetyl group in fully acetylated glycals is cleaved to form the "Ferrier" glycosyl cation that in turn is attacked by nucleophiles at the C1 position. After an allylic shift, the reaction yields 2,3-unsaturated glycosides, a class of glycosides that is relevant for the synthesis of natural products4 and pharmaceuticals such as 2-deoxyglycosides,5 C-glycopyranosyl arenes, and heteroaranes.6 The reaction can also be observed for glycals bearing other participating protecting groups, i.e., benzoyl.3

Due to their short-lived nature, the exact structure of the intermediate of the Ferrier rearrangement remains elusive. It has been postulated that cleavage of the C3-acetyl group is eased by neighboring group participation (anchimeric assistance) of the C4-acetyl group, leading to a dioxolenium-type ion I.7 However, so far no direct experimental evidence has been available to determine whether the underlying structural motif is indeed a dioxolenium ion I or a resonance-stabilized oxocarbenium ion II. Recently, a Ferrier cation with protonated acetyl groups was characterized by NMR spectroscopy in superacids. As protonation of acetyl groups drastically reduces nucleophilicity, participation cannot be observed under these conditions. In a previous study of glycosyl cations, it was shown that C4-acetyl groups, contrary to C2-acetyl groups, do not participate in superacids.8

In the past several years, it has been demonstrated that glycosyl cations can be isolated in the gas phase and characterized using infrared (IR) spectroscopy. In combination with density functional theory (DFT), the underlying structural motif can be unambiguously identified. Thereby, it has been shown that neighboring and remote acetyl groups can stabilize a glycosyl cation by forming a covalent bond to the anomeric carbon.10−14 Here, we use gas-phase cryogenic IR spectroscopy and DFT to elucidate the structure of the Ferrier glycosyl cations generated from acetylated glucal and galactal.

A detailed description of the experimental setup can be found in the Supporting Information. Briefly, Ferrier cations are generated by nanoelectrospray ionization (nESI) followed...
by in-source fragmentation of sodiated glycal precursor ions. Representative mass spectra (Figure 1) reveal that fragmentation readily occurs for acetylated glycols, while it cannot be observed for unprotected glycols (Figures S1 and S2). This is mainly attributed to acetate being a better leaving group than hydroxide and the anchimeric assistance of neighboring acetyl groups.

The generated Ferrier cations are isolated using a quadrupole mass filter and subsequently collected in a hexapole ion trap, where the ions are cooled to 90 K. A beam of superfluid helium nanodroplets is guided through the ion trap, picking up the ions, cooling them to 0.4 K, and leading them to a detection region. Here, the beam of ion-doped helium droplets overlaps with an IR beam (1000–1800 cm⁻¹) that is produced by the Fritz Haber Institute free-electron laser (FHI FEL). The absorption of multiple resonant IR photons leads to release of the analyte ions from the droplets that are subsequently detected by a time-of-flight mass spectrometer. Plotting the ion count as a function of the IR wavenumber leads to a highly resolved IR spectrum of the analyzed ion. To derive structural information, the experimental IR spectra were linked to quantum chemically modeled structures. The conformational space of the Ferrier cations was explored using the genetic algorithm FAFOOM that allows for sampling of rotatable bonds and ring puckers. Each generated structure was preoptimized by the dispersion-corrected PBE +vdWTS density functional as implemented in FHI-aims using light basis set settings. The conformational search mainly yielded dioxolenium ions I and oxocarbenium ions II, but also dioxolenium-type structures in which the C4-acetyl group interacts remotely with the anomeric carbon (remote participation). A subset of the lowest-energy structures of each type of ions was reoptimized, and frequencies were computed at the PBE0+D3/6-311+G(d,p) level of theory using Gaussian. The computed IR spectra were normalized and scaled by a factor of 0.965. Cremer–Pople coordinates were used to assign ring puckers. Energetics, ring puckers, and coordinates of the reoptimized structures can be found in the Supporting Information.

The IR spectrum of the Ferrier glucosyl cation shows a complex signature that can be interpreted using the computed spectra of low-energy conformers (Figure 2a). The experimental IR signature matches the theoretical spectrum of dioxolenium-type glycosyl cation I, exhibiting a 5E ring puckers in which the carbonyl oxygen of the C4-acetyl group forms a covalent bond (1.53 Å) with the C3 atom (Figure 2b). The free energy of this structural motif is generally more favorable than that of oxocarbenium ions II that adopt a distorted 5E ring puckers without direct participation of protecting groups (Figure 2c). Generally, the most diagnostic absorption bands are found above 1500 cm⁻¹. Bands at 1506 and 1550 cm⁻¹ correspond to the symmetric and antisymmetric O−C−O stretches, while the signal at 1646 cm⁻¹ represents a C=C stretching vibration. The pronounced absorption band at 1750 cm⁻¹ can be attributed to the C=O stretch. Features below 1300 cm⁻¹ result from C−C and C−O stretching vibrations, while the bands around 1400 cm⁻¹ are due to C−H bending modes. Although the absorption bands in the region below 1500 cm⁻¹ are usually less diagnostic, theory fits the experiment surprisingly well. The spectral signature of the energetically unfavored (+29 kJ mol⁻¹) oxocarbenium-type species II on the other hand does not match the experimental...
spectrum. While some signals seem to overlap, others are not present in the experimental spectrum and vice versa. In addition, none of the oxocarbenium-type species II matches the experimental spectrum particularly well. The spectra of the energetically less favored dioxolenium ion featuring remote participation (+49 kJ mol\(^{-1}\)) do also not correspond to the experimental spectrum (Figure S7). We can therefore conclude that the underlying structural motif of the Ferrier glucosyl cation exhibits anchimeric assistance of the C4-acetyl group to form dioxolenium-type I structures.

Similar results were obtained for the Ferrier galactosyl cation (Figure 3a). The computed spectrum of the dioxolenium-type I structure overwhelmingly matches the experimental spectrum. Besides the highly diagnostic vibrations above 1500 cm\(^{-1}\), here also the fingerprint region from 1000 to 1300 cm\(^{-1}\) agrees exceptionally well. Again, the dioxolenium-type I ion features a covalent bond (1.52 Å) between the carbonyl oxygen of the C4-acetyl group and the C3 atom and adopts an \(E\) ring pucker (Figure 3b). The lowest-energy oxocarbenium-type II structure adopts a \(Z\) ring pucker but exhibits a free energy that is 30 kJ mol\(^{-1}\) larger than that of the lowest-energy dioxolenium-type I structure (Figure 3c). Not surprisingly, the spectral signatures of the oxocarbenium-type II structures generally match the experiment rather poorly. The Ferrier galactosyl cation adopts a dioxolenium-type I structure, formed by neighboring group participation of the C4-acetyl group.

In summary, we unraveled the detailed molecular structure of the key intermediate of the Ferrier rearrangement reaction. Direct experimental characterization by gas-phase cryogenic IR spectroscopy combined with first-principles density functional theory unambiguously revealed that dioxolenium-type ions are the underlying structural motif of Ferrier glycosyl cations. Ions generated from both glucal and galactal, stabilization of the positive charge at C3 via participation of the C4-acetyl group is clearly favored over delocalization of the charge within the pyranose ring. The findings provide unprecedented insights into the mechanism of the Ferrier rearrangement and showcase how such experiments can support the development of novel building blocks for the synthesis of 2,3-unsaturated glycosides.
